Annotation. Aim: Nowadays increasing blood pressure is the most important risk factor of coronary, cerebral and renal vessel diseases. Epidemiological studies indicate that Physical inactivity adversely affects the blood pressure in postmenopausal women. The purpose of this study was to determine the impact of aerobic on body composition and blood pressure in postmenopausal women. Methods: 20 healthy postmenopausal women with similar age and weight were randomly divided in intervention and control groups. Subjects completed an informed consent form and health history questionnaire. The intervention group was trained in an aerobic exercise program for 8 weeks (3 sessions weekly). Weight, body fat percentage (BF%), body mass index (BMI), waist to hip ratio (WHR), Lean body mass and blood pressure (BP) were measured in the beginning and the end of the study for all of the subjects. Data were analyzed by the Paired t-test and independent t-test. Results: The results showed that BF%, WHR, BMI decreased and Lean body mass increased significantly in training group after 8 weeks training (P<0.05), while BF% significantly increased in control group. The results show that resting systolic BP (SBP) and diastolic BP (DBP) decreased following both training modes; while it remained unchanged in control subjects (p>0.05). Conclusions: It seems that a period of aerobic training for 8 weeks can be effective as a non-pharmacological treatment strategy for improvement some physical fitness and body composition indexes, blood pressure in postmenopausal women.

Key words: aerobic, training, blood pressure, women, postmenopausal.

Introduction
As medical technologies have developed in modern society, average human life span has been gradually extended and mortality rate has been decreased, so the number of old people is increasing worldwide (Hyung and Kim., 2001). As a result, issues in aging of population along with maintaining the quality of life have become serious problems (Hong et al., 2005). The proportion that the elderly population takes is rapidly increasing in Iran.

In this population, there is a higher observed prevalence of chronic diseases such as hypertension (Nesterov et al., 2009); especially in women. Currently, it is estimated that among postmenopausal women, the prevalence of hypertension may reach 80% (De Lyra Júnior at al., 2006). The treatment of hypertension includes pharmacological and nonpharmacological interventions (Bacon et al., 2004; Roberts et al., 2002). Among the nonpharmacological interventions, regular exercise has been recommended in the prevention (Cornelissen et al., 2010). Among the principal physiological benefits of physical training in hypertensive patients are reductions in heart rate (HR) and peripheral vascular resistance (Collier et al., 2008). These factors are related to the fall of systolic and diastolic blood pressure (BP) (MacDonald et al., 1999). In addition to improvements in BP, aerobic training is associated with a reduction of Weight, body fat percentage (BF%), body mass index (BMI) and waist to hip ratio (WHR), which often is above the reference values in hypertensive subjects (Ferrara et al., 2002).

The efficacy of aerobic exercise for lowering blood pressure (BP) in postmenopausal women, especially those with only modest BP elevations, has not been established. Importantly, aerobic exercise training often results in increases in maximal aerobic capacity and reductions in body weight. Because maximal aerobic exercise capacity and body weight are independently associated with BP in humans (Blau et al., 1984; McGowan et al., 2006); at least some of the BP-lowering influence of regular exercise in a particular population may be related to these factors rather than to a primary effect of exercise per se (Fagard., 2006).

However, there are controversies about the effects of regular exercises compared with the studies on blood pressure. Beside the studies reporting that there have been positive developments in the blood pressure as a result of acute exercise (Berg et al., 1983; Fogel et al., 1994), there are also studies stating that there have been improvements as a result of not acute but long term exercises (Sucic and Oreskovic 1995; Yanagibori et al., 1993).

The effects of aerobic exercise training on cardiovascular and metabolic parameters in hypertensive postmenopausal women remain unclear and controversial. Some studies indicate beneficial effects (MacDonald et al., 1999; Moraes et al., 2011); and others report no significant changes (Church et al., 2007; Stewart et al., 2005). These effects seem to depend on duration, intensity, and frequency of the exercise (Moraes et al., 2011; Manson et al., 2002).

This study aimed to evaluate the effects of 8 weeks of aerobic on body composition and blood pressure in postmenopausal women.

Materials and methods
Subjects
The target population consisted entirely of postmenopausal women in city of Rasht in Iran. Among them 20 healthy postmenopausal women with similar age and weight were randomly divided into intervention and control groups. Also, none of the subjects were taking any medication, including antihypertensives or aspirin, and all were non-
smokers. The condition of the study was thoroughly explained to all subjects, and written informed consent was subsequently obtained. The protocol was approved by the Ethics Committee of Islamic Azad University Rasht Branch, Guilan, Iran.

**Anthropometrics**

Whole-body plethysmography (Bod Pod; Life Measurement Inc., Concord, CA, USA) was used to assess body composition (Katch et al. 1967), and body weight was measured using the Bod Pod scale. Height was measured using a stadiometer to the nearest 0.5 cm, and body mass index was calculated as weight (kg) per height $^2$ (m$^2$).

**Haemodynamic monitoring**

Blood pressure was measured by a trained investigator by standard sphygmomanometry following a quiet rest for 15 min in the supine position. SBP and DBP were measured manually at the brachial artery after the resting period and at the start of each testing session using the first and fifth Korotkoff sounds, according to American Heart Association standards (Kirkendall et al. 1981).

**Exercise training**

The exercise group participated in an 8 week supervised aerobic exercise program. The exercise group trained for 50 min/day, and the program was composed of 3 steps: warm-up for 10 min, aerobic exercises for 30 min (which consisted of treadmill running for 30 min at intensity of 60–80% of their heart rate reserve (HRR)), and cool down for 10 min. The exercise group trained for 3 day/week for 8 weeks, while the control group was asked to maintain their normal sedentary activities. Exercise intensity was monitored during the training sessions by using a Polar real time system (Polar S610, Finland).

**Statistical Analysis**

SPSS statistical software (version 18) was used to analyze. Both descriptive (mean and standard deviation) and inferential statistical were used to analyze the data. Paired t-test and independent t-test were applied.

**Results**

**Subjects**

Subject age data are present in table 1. The results showed that BF%, WHR, BMI decreased and Lean body mass increased significantly in training group after 8 weeks training ($P<0.05$), while BF% significantly increased in control group. Saavedra et al., (2007), applied water aerobics on healthy 43.1 ± 9.7 years old middle-aged females twice a week for 8 months. They established that the values of the last tests of BW and BFP after 8-month exercise were significantly different from the

**Discussion**

Epidemiologic studies have shown that sedentary life relates to the increases of age and heart disease. Obesity is one of the factors that cause heart disease. Beneficial effects of aerobic training programs on body composition and blood pressure have been evaluated. In the current study, BMI and fitness were both independently associated with the risk of hypertension. The results showed that BF%, WHR, BMI decreased and Lean body mass increased significantly in training group after 8 weeks training ($P<0.05$), while BF% significantly increased in control group. Saavedra et al., (2007), applied water aerobics on healthy 43.1 ± 9.7 years old middle-aged females twice a week for 8 months. They established that the values of the last tests of BW and BFP after 8-month exercise were significantly different from the
Based on previous studies, aerobic exercise, adds up the exercise capability of your body to use fat as a substrate increases and total fat oxidation during. In addition, there is a high correlation between the content within the muscle and insulin resistance. It may be suggested that the body mass increases due to increased blood flow and capillary in skeletal muscle and adipose tissue. Lipolyze triacylglycerol is high, and the transfer of fatty acids from blood to muscle sarcoplasm is high; these are the effects on fat during exercise and these effects support by activation of certain enzymes in the oxidative pathway, supports this process. Acrobic exercise activates lipoprotein lipase and increased lipoprotein lipase (LPL) activity may play an important role in reducing insulin resistance during exercise (Irving et al., 2008; Fenkci et al., 2006). Elderly women have increased pulse and blood pressure compare to young people. However, exercise decreases the blood pressure and gives positive effects (Jeon et al., 2010). During exercise, changes in blood pressure is due to the activation of sympathetic nerves and the reduction of parasympathetic nerve stimulation which causes increase in the systolic pressure but the diastolic pressure maintains it’s level. However, exercise causes drops in both systolic and diastolic pressure (Martynov, 2007). The results show that resting systolic BP (SBP); RE, pre 13.10±1.52 vs post 11.40±1.26; CG, pre 12.60±0.96 vs post 12.60±1.34 mm Hg, P=0.001; and resting diastolic BP (DBP); RE, pre 8.10±0.99 vs post 7.60±1.03; CG, pre 8±0.47 vs post 8.60±0.23 mm Hg, P=0.035; decreased following both training modes; while it remained unchanged in control subjects (P>0.05).

Our findings are similar to those reported in the Heritage family study, 26 which showed small changes (0±3mmHg) in resting SBP and DBP in normotensive to mildly hypertensive subjects following a longer and progressively more intense training programme (20 weeks, 55–75% VO2max) (Wilmore et al., 2001). Hagberg et al., (1989), also demonstrated a decrease in SBP (20mmHg) in hypertensive men following 9 months of low- to moderate-intensity aerobic training, with a concomitant decrease in DBP (11–12mmHg) (Hagberg et al., 1989). Fagard, (2006), who has shown that AE decreases in BP in normotensives of 0.5 (SBP)mmHg and 0.2 (DBP)mmHg with even greater reductions in resting BP in hypertensives (6.9 and 4.9mmHg in SBP and DBP, respectively) (Fagard., 2006). One previous study reported that 4 months of endurance training in middle-aged men resulted in no changes in resting SBP and 0±5mmHg decrease in resting DBP. Our results support these earlier studies (Hagberg et al., 1989; McGowan et al., 2006).

Clarkson et al., (1999), indicated that endothelium-dependent dilation in young men enhanced by aerobic exercise training was beneficial in preventing CV Diseases. These exercises maintain a high level of fitness, prevent age-related decline of microvascular NO-mediated vasodilator function, the higher levels of NO confer anti-atherogenic benefit and prevent microvascular dysfunction in humans (Clarkson et al., 1999). It is worth mentioning that regular moderate intensity exercise can be used to improve metabolic risk factors such as insulin and leptin levels in overweight/obese postmenopausal women (Frank et al., 2005). Furthermore, exercise per se has been shown to be an important factor in the reduction of hypertension by decreasing the elevated activity of the sympathetic nervous system (SNS). According to Mueller, exercise may reduce the resting blood pressure and sympathetic outflow even in normal individuals (Mueller, 2007). It is important to point out that almost two decades ago two cohort studies also demonstrated that regular physical activity prevents the development of hypertension, moreover it has been found to lower the blood pressure in hypertensive individuals (Greenland et al., 2010; Vianna et al., 2012).

Aerobic exercise training promotes the reduction of risk factors of cardiovascular diseases in postmenopausal obese hypertensive women. Results of this work can be employed by clinicians to help postmenopausal women to overcome the increased risk of morbidities associated with menopause.

**Conclusion**

Based on these findings, it seems that a period of aerobic training for 8 weeks can be effective as a non-pharmacological treatment strategy for improvement some physical fitness and body composition indexes, blood pressure in postmenopausal women. Furthermore, there is a need for appropriate health education emphasizing the importance of cardiovascular health at this level of education.

**Acknowledgement**

The authors would like to thank the postmenopausal women for their willing participation in this study.
